study seems to favor the superoxide($Fe^{III}O_2^-$)[11,12] over the neutral $O_2(Fe \rightleftharpoons O_2)$ model,[13,14] since even the $O_2$ in "base-free" Fe(TPP)$O_2$ is close to $O_2^-$.

Recently, Duax et al.[1] analyzed crystallographic data on 85 20-oxopregnanes and found that in virtually all cases the value for $\tau$ (the C(16)–C(17)–C(20)–O(20) torsional angle) lay between 0 and −46° (see Figure 2 in ref 1). They inferred a "conflict between X-ray data and force-field calculations", since such calculations,[2] as well as earlier quantum mechanical calculations,[3] give a minimum energy value for $\tau$ of −60°. Duax et al.[1] reject the proposal of Schmit and Rousseau[2] that this deviation comes from crystal packing forces. Moreover they conclude that the 6 kcal/mol barrier to complete rotation around $\tau$ calculated by Schmit and Rousseau is unrealistically low and that this barrier "might be better represented by rigid-molecule results", suggesting values in excess of 50 kcal/mol, with the $\tau = 120°$ conformation about 25 kcal/mol higher than the $\tau = -30°$ conformation.

In this communication we show that the apparent conflict is due to the use of an inadequate force-field model and that the putative discrepancies are not observed when energy refinement using MM2CDC (hereafter referred to as MM2)[4] is employed. As part of our studies of steroid structures, we carried out force-field calculations on a number of corticosteroids, as well as on models for the steroid D ring. For compounds without a 16$\beta$ substituent the minimum-energy $\tau$ values range from −4 to −20°, with generally small deviations from the crystal values (Table I).

As noted by Duax et al.[1] steroids with a 16$\beta$ substitution have crystal structures with $\tau = -109°$ as well as −20°. Our calculations on 16$\beta$ substituted and unsubstituted steroids (Figure 1) show a number of local minima in the torsional potential in both series,

Table I. Comparison of Selected $\tau$ Values from X-ray and MM2 Calculations

| molecule | X-ray | MM2 |
|---|---|---|
| progesterone | −6.6 | −4.2 |
| 16$\beta$-methylprogesterone | −108.0 | −110.0 |
| 21-hydroxyprogesterone | −11.1 | −4.6 |
| cortisone | −28.9 | −19.7 |
| cortisol | −30.1 | −19.4 |
| 9$\alpha$-fluorocortisol | −26.8 | −18.0 |
| 9$\alpha$-chlorocortisol | −28.2 | −18.4 |
| 9$\alpha$-bromocortisol | −18.4 | −17.7 |
| 9$\alpha$-fluorocortisone | −(28.9)[a] | −20.4 |
| 17$\alpha$-progesterone acetate | −18.9 | −8.9 |
| 6$\alpha$-methyl-9$\alpha$-fluoroprednisolone | −16,−32 | −18.0 |
| 6$\alpha$-hydroxyprogesterone | −9.0 | −4.0 |

[a] This structure generated by adding a 9$\alpha$-fluorine atom to the heavy-atom coordinates of cortisone.

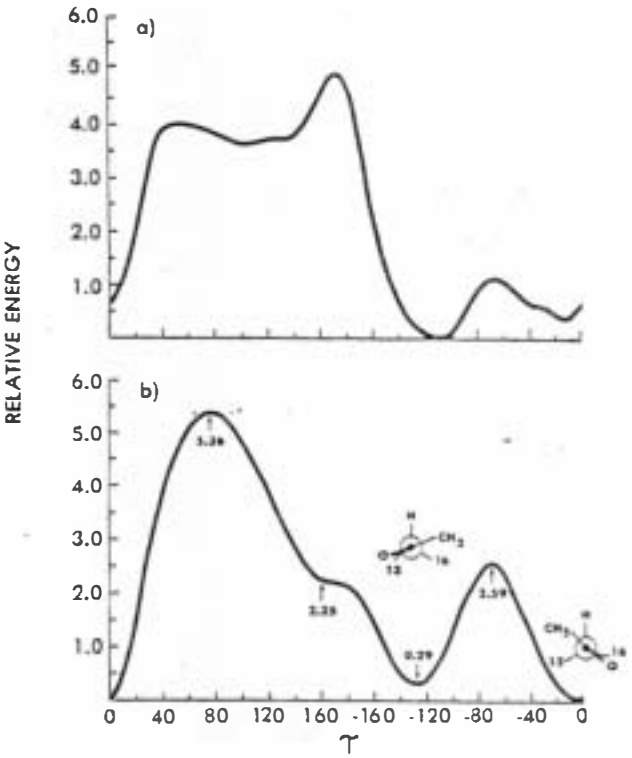

Figure 1. (a) Energy as a function of $f(\tau)$ for 16$\beta$-methylprogesterone (II); units of energy in kcal/mol. (b) Energy as a function of $f(\tau)$ for progesterone (I); units of energy in kcal/mol.

the relative energies of which are determined by steric interactions when the C=O bond is close to elipsing the adjacent C-C bond. The local minima in the potential at $\tau = 0$ and −120° come from the tendency for the C=O to eclipse the C(16)–C(17) and C(13)–C(17) bonds, respectively.

The MM2 force field for aliphatic carbonyl compounds[4] was developed by one of us (S.P.) to model the tendency of aliphatic groups to eclipse carbonyl groups. Additionally, the torsional potentials in MM2 have been confirmed for accuracy by ab initio calculations[5,6] at several levels. These ab initio rotational potentials show a clear preference for carbonyl groups to eclipse methyl (or methylene) groups relative to eclipsing hydrogens.[7] Carbonyl

(4) MM2 is available from the Quantum Chemistry Program Exchange (Allinger, N. L.; Yuh, Y. H. *QCPE*, 1980, *12*, 395. Profeta, S., Jr. *QCPE Bull.* 1981, *1*, 57). These programs contain the carbonyl force field discussed herein. The calculated $\tau$ values reported in Table I represent those obtained by energy minimization of the crystal-structure coordinates. The functions in Figure 1 were derived by fixing $\tau$ to a given value and refining the remaining degrees of freedom.
(5) Profeta, S., Jr.; Allinger, N. L., unpublished data. This work details STO-3G and 6-31G calculations of the rotational potential functions of 2-butanone, 2-pentanone, and 3-pentanone. Similar calculations were also performed on the conformers of 2-methylcyclohexanone. In all cases, both calculation and experiment indicate at least a 1 kcal/mol preference for the C=O/C–C eclipsed conformation over the C=O/C–H.

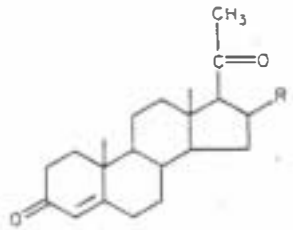
groups gauche to methyl, methylene, or hydrogen functions are calculated as relative maxima. Thus, deviations from $\tau = 0$ and $-120°$ must come principally from steric repulsion.

Eclipsing of the 17$\alpha$ H by the C=O is less favorable despite the tendency of the C=O to eclipse nearby bonds.[5,7] Such a conformation places the C(21) methyl group over the D ring and in repulsive steric contact with C(18) and C(16). In fact, this occurs in only one case analyzed by Duax et al.[1] and is due to a steric effect from a large 17$\alpha$ substituent.

MM2 predicts the observed minimum-energy angle in the crystal for progesterone as well as for 16$\beta$-methylprogesterone (II) ($\tau = -110°$). Thus, *state of the art* molecular mechanics is



I, R = H
II, R = $CH_3$

able to reproduce the low-energy structures for these compounds. The failure of the previous force-field calculations[2] is due, in part, to lack of inclusion of appropriate torsional terms that model the observed tendency of a C=O bond to eclipse neighboring aliphatic bonds. MM2 contains such terms.[4] It is more difficult to explain why extended Hückel theory fails in this connection, but in that study[3] the energy was evaluated as a function of $\tau$ at only 60° increments, and no attempt was made to optimize the geometry as a function of $\tau$. Thus, the energy of conformations having $\tau = 0$ and $-120°$ was probably overestimated by steric effects.

The average difference between the X-ray and MM2-calculated values for $\tau$ (Table I) is 7°, the same as the mean deviation of $\tau$ for the 21 unsubstituted progesterone crystal structures. The calculated values show a more eclipsed C—C—C=O orientation than the X-ray. We cannot rule out either crystal packing forces or inadequacies in the force fields as a source of this systematic discrepancy but note that such differences in dihedral angles would correspond to energy differences of 0.1–0.2 kcal/mol.

The conclusion of Duax et al.[1] that the rigid rotation surface of Schmit and Rousseau[2] is an adequate representation of the energy as a function of $\tau$ is almost certainly wrong. In the study of Schmit and Rousseau and in this study a difference in energy of 5–10 kcal between the low-energy regions ($\tau = 0$ to $-120°$) and the high-energy regions ($\tau = 60–180°$) was observed. The CD results of Wellman and Djerassi[8] suggest that the two local minima found in our study differ in energy by 1.1 kcal/mol in progesterone. Again, the dipole moments at 25° of progesterone[9] (2.7 D) and 16$\beta$-methylpregnane-3,20-dione[10] (2.66 D) argue strongly against the suggestion by Duax et al.[1] that the energy difference between the $\tau = -20°$ and $-110°$ conformations has been "greatly underestimated". We calculate dipole moments for the minimum-energy conformations of progesterone ($\tau = -4°$ and $-135°$) to be 1.91 and 3.62 D. The corresponding values for $\tau = -13$ and $-110°$ for 16$\beta$-methylprogesterone are 1.78 and 3.12 D, respectively. Only by assuming a Boltzmann average of these two conformers can one arrive at dipole moments (2.73 D from 68% $\tau = -4°$ and 32% $\tau = -135°$ for progesterone and 2.74 D from 66% $\tau = -110°$ and 34% $\tau = -13°$ in 16$\beta$-methylprogesterone)[11] in reasonable agreement with experiment. Thus, our results indicate that in solution both conformers are significantly populated, as is also maintained by Wellman and Djerassi[8] and Allinger et al.[10] Lastly, the existence of the $\tau = 162°$ conformation in a compound with a large 17$\alpha$ substituent rules out the suggestion of Duax et al.[1] that its energy is ~30 kcal higher than the minimum.

Given the small 0.3 kcal/mol calculated energy difference between $\tau \sim 0$ and $\tau \sim -120°$ conformers for progesterone, how can one explain a 76:0 ratio of $\tau \sim 0$ to $\tau \sim -120°$ conformers for progesterone, but a 3:4 ratio of these conformers with a 16$\beta$ substituent in crystal structures? A possible explanation is the fact that the $\tau \sim 0°$ conformation points the C=O away from the molecule and thus allows favorable intermolecular contacts with this group; the $\tau \sim -120°$ conformation has the C=O less accessible to intermolecular interactions. For example, the closest intermolecular contact in the crystal of progesterone ($\tau = 7°$) is between C-21 (methyl) and O-3. In the $\tau \sim 0°$ conformation, this distance (3.5 Å) gives an attractive interaction. If $\tau \sim -120°$, then the closest contact would be between O-20 and O-3 and could be electrostatically repulsive. Thus, the distribution of both 16-hydrogen and 16-substituted steroids may be skewed toward favoring the $\tau \sim 0°$ conformation by intermolecular packing, compared to the relative preferences calculated (Figure 2, ref 1) for the isolated molecules.

In summary, there is no conflict between X-ray structural data and state of the art force-field calculations. The preponderance of $\tau = -20°$ conformations for progesterone and the tendency for 16$\beta$ substitution to stabilize the $\tau = -120°$ conformation are found in both crystal and calculated structures. Moreover, both CD and dipole moment results show that the $\tau = -20$ and $-120°$ conformers are sufficiently close in energy to be significantly populated in solution, and presumably of "potential" importance in drug-receptor interactions. The barrier between $\tau = -20$ and $-120°$ is small (2.5 kcal/mol) and that between $\tau = -180$ and $-20°$ is somewhat larger (5 kcal/mol); however, both barriers can be traversed rapidly.

(11) All calculations were done with a dielectric constant of 1.5. While the comparison of 16$\beta$-methylprogesterone to 16$\beta$-methylpregnane-3,20-dione is not "exact", we have found, in the absence of an experimental value for the moment of 16$\beta$-methylprogesterone, that the corresponding $\Delta^4$-saturated system provides a very close reference value. It should be noted that the MM2 calculated dipole moments of cyclohexanone and cyclohexenone are very similar (2.91 vs. 2.96 D). While these values are both slightly smaller (~5%) than the corresponding experimental values, they are internally consistent and sufficiently similar to make the 16$\beta$-methyl systems comparison valid. Furthermore, if the equilibria in the progesterone systems were as one-sided as has been suggested,[1] then the observed dipole moments would be significantly smaller; e.g., for progesterone, for a 90:10 ratio of $\tau = -10$ to $\tau = -135°$ ($\Delta G = 1.31$ kcal/mol) the calculated moment is 2.14 D, *far* lower than that observed. Similar arguments pertain to the 16$\beta$ systems. The dipole moment for progesterone is calculated to be 3.30 D at $\tau = -100°$, 3.61 D at $\tau = -135°$, 1.90 D at $\tau = -10°$, and 2.02 D at $\tau = -30°$. Thus, no single conformation is consistent with both the energy and dipole moment and a Boltzmann average of two conformations is required to explain the data. A referee has expressed skepticism about the validity of the second minimum $\tau$ values used in the dipole moment calculations. For progesterone, we see at $\tau = -135°$ the repulsive interaction between the C(18) group and O(20) appears to be greater than that between the 16$\beta$ hydrogen and the C(21) group. Logically the minimum shifts toward $-110°$ in 16$\beta$-methylprogesterone from $-135°$ in progesterone in response to the C(21)–16$\beta$-methyl repulsion. However, the repulsive interaction between O(20) and 16$\beta$ methyl amounts to 0.75 kcal, a value sufficient enough to shift the minimum $\tau$ value to $-13°$ and absolute minimum to $-110°$. This fact, however, should not render the $\tau = -13°$ conformation "prohibited".
